Constraint Solving & Symbolic Execution

Symbolic execution

Symbolic execution is a powerful approach in binary analysis which consists of exploring all the possible paths a program can take by using symbolic values as input.

Execution starts normally, and whenever a decision whether to take branch or not has to be made, the current state of the program is **duplicated** and both branches are executed, keeping track of the **conditions** needed by each one.

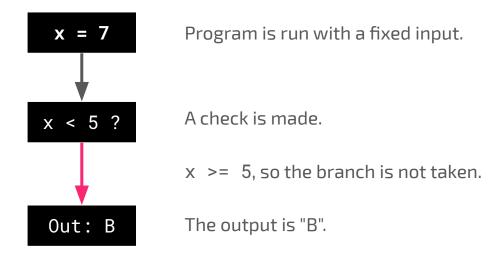

```
int main(void) {
      unsigned x;
 3
     scanf("%d", &x);
 4
 5
      if (x < 5)
 6
        puts("A");
      else
8
        puts("B");
9
10
      return 0;
11
```

Normal execution

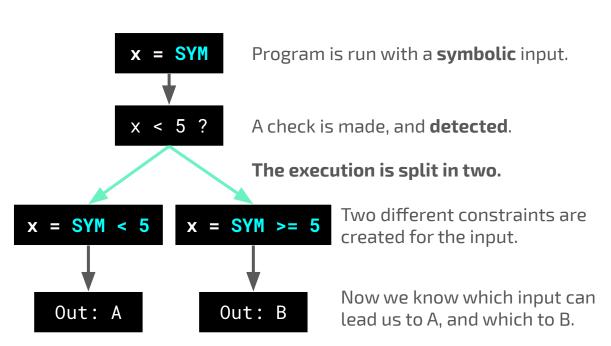

```
int main(void) {
      unsigned x;
 3
     scanf("%d", &x);
 4
 5
      if (x < 5)
 6
        puts("A");
      else
8
        puts("B");
9
10
      return 0;
11
```

Normal execution

```
int main(void) {
     unsigned x;
3
     scanf("%d", &x);
4
5
     if (x < 5)
6
        puts("A");
     else
8
        puts("B");
9
10
     return 0;
11
```

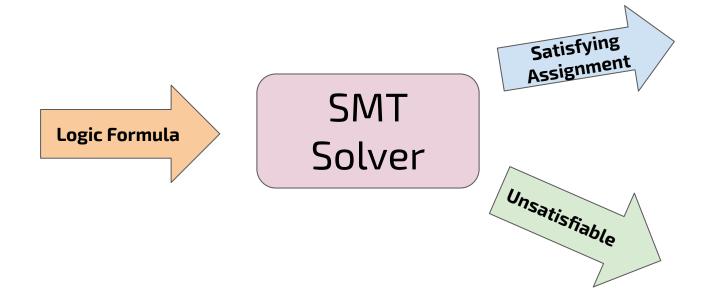

```
int main(void) {
     unsigned x;
     scanf("%d", &x);
 5
     if (x == 0xa5f4e321)
        puts("A");
     else
        puts("B");
10
11
      return 0;
```

Constraint programming

In short, "constraint programming" means we do not specify a step or sequence of steps to execute, but rather the properties of a solution to be found.

This technique is very useful in reverse-engineering: specific sets of constraints often need to be satisfied in order to "crack" a program.

SMT solvers

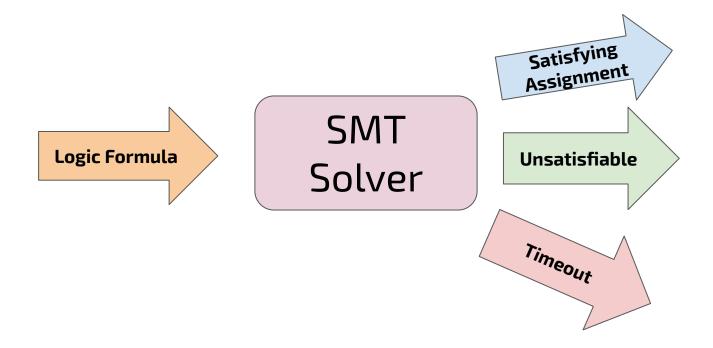

SMT solvers

SMT (Satisfiability Modulo Theories) is a generalization of the boolean satisfiability problem. In **boolean logic** we only have two possible values (0, 1), in the SMT more complex values can be expressed as multiple boolean values.

An SMT solver is a program which can automatically determine if a certain **set of constraints** (expressed in first-order logic) is **satisfiable**, and if so, find the solution(s).

SMT solvers - NP Problem

SMT solver

Boolean SAT + Theories:

BitVector

Integer

Uninterpreted Function

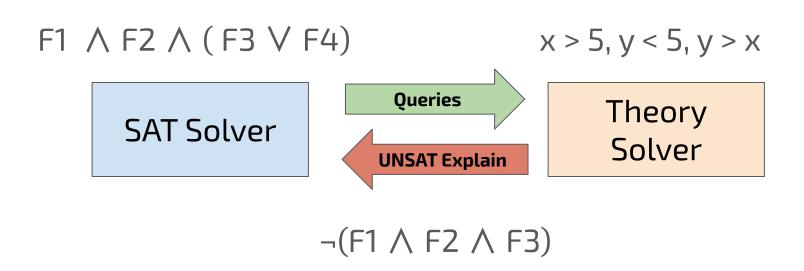

Array

SAT Solver

Conjunctive Normal Form

SAT Solver + Theories = SMT

$$x > 5 \land y < 5 \land (y > x \lor y > 3)$$

The Z3 SMT solver

Z3 is a powerful SMT theorem prover and solver.

We will take a look at its Python3 API and go through the main kind of problems it can solve:

- Linear integer/real arithmetic equations.
- Non-linear integer/real arithmetic equations.
- Optimization problems.

Z3: basic variable types

z3.Int('x')	Unbounded integer variable.
z3.Real('x')	Unbounded real variable.
z3.Bool('x')	Boolean variable.
z3.BitVec('x', <length>)</length>	Bit vector: ordered sequence of bits.
z3.FP('x', <type>)</type>	Floating point variable.
z3.String('x')	String variable (not really a classic string).

Z3: expressions

Every variable created with Z3 can be used symbolically to create expressions:

```
>>> x = z3.Int('x')
>>> y = z3.Int('y')

>>> x + y
x + y

>>> x - y < 4
x - y < 4
```

```
>>> type(x)
z3.z3.ArithRef
>>> type(x + y)
z3.z3.ArithRef
>>> type(x - y < 4)
z3.z3.BoolRef</pre>
```

Z3: constraint solver

A set of expressions (aka constraints) can be checked for satisfiability and, if satisfiable, evaluated:

```
x = z3.Int('x')
y = z3.Int('y')
z = z3.Int('z')

solver = z3.Solver()
solver.add(x > y)
solver.add(y > z)
solver.add(z >= 3)
solver.add(z <= 5)</pre>
```

```
>>> solver.check()
sat
>>> model = solver.model()
>>> model.eval(x)
5
>>> model.eval(y)
4
>>> model.eval(z)
3
```

Z3: simple non-linear equation system

```
\begin{cases} y = x^2 - 4 \\ y - z = 10 \\ x + 3y + z = -6 \end{cases}
```

```
[
    y = 0.4713602229,
    x = 2.1145591083,
    z = -9.5286397770
]
```

```
x = z3.Real('x')
2 | y = z3.Real('y')
3 \mid z = z3.Real('z')
   solver = z3.Solver()
   solver.add(y == x**2 - 4)
   solver.add(y - z == 10)
   solver.add(x + y + z == -6)
10
   solver.check()
   m = solver.model()
13
   print(m)
```

Z3: simple optimization

```
x = z3.Real('x')
Constraints: \begin{cases} x < 4 \\ y - x < 2 \end{cases}
                                         |2| y = z3.Real('y')
                                         3 value = z3.Real('value')
                                           opt = z3.Optimize()
                                         6
value(x, y) = x + 2y
                                            opt.add(x < 4)
                                           opt.add(y - x < 2)
                                            opt.add(value == x + 2*y)
                                        10
                                            opt.maximize(value)
                                            opt.check()
          value = 11
                                        13
                                            print(opt.model())
```

Z3: conditional logic

```
def f(a, b):
   if a < 1:
       return a
   if b > 1:
        return a + b
    return b
def f(a, b):
    if2 = z3.If(b > 1, a + b, b)
    if1 = z3.If(a < 1, a, if2)
    return if1
```

```
solver = z3.Solver()
x = \overline{z3.Int('x')}
y = z3.Int('y')
solver.add(f(x, y) == 6)
solver.check()
print(solver.model())
     [y = 5, x = 1]
```

Angr is a binary analysis framework for both static analysis and symbolic execution. It's written in Python, which makes it simple to use

Python3

Check out <u>angr.io</u> for documentation, tutorials and working examples! Really, DO IT, there's much more to know...

The **Project**: every time you work with angr, you'll need to create a "project". A project takes a binary and loads it, along with the needed libraries, and extracts basic information.

```
>>> proj = angr.Project('/bin/true')
>>> proj.arch
<Arch AMD64 (LE)>
>>> proj.entry
0x401670
>>> proj.filename
'/bin/true'
```

The SimulationManager: once a project is created, we can create an instance of a sim. manager from it. The SM is the core of angr, and controls how the binary is executed and dynamically analyzed. The SM takes a **state** from which to start execution as argument (by default the entry point).

```
>>> sm = proj.factory.simgr()
>>> sm
<SimulationManager with 1 active>
>>> sm.active
[<SimState @ 0x401670>]
```

The **SimState**: it's a class representing a simulation state, which is a snapshot of the state of the binary at a certain point of execution: **registers**, **processor flags**, **memory**, **etc.**

States can be created or modified to alter the program execution. They are organized by the SM in different stashes, with different meanings. The most important are the active stash and the deadended stash.

Create a SimState (for example from the entry point):

```
>>> state = proj.factory.entry_state()
<SimState @ 0x401670>
```

Customize the state:

```
>>> state.regs.rbp = state.regs.rsp
>>> state.mem[0x1000].uint64_t = state.regs.rdx
>>> ...
```

Before starting the execution, and whenever a branch is encountered, a new SimState is put in the *active* stash.

States in the active stash are **executed in "parallel" (one basic block** at the time), until they reach a dead end (for example return from main(), exit(), etc.).

When a state reaches a dead end and can no longer advance, it is put in the **deadended** stash.

The workflow when working with angr for symbolic execution is more or less always the same:

Create a Project.

Create or choose a SimState to start from.

Create a SimulationManager (pass the state to it).

Simulate using .step(), .explore() or .run().

Optional: monitor the stashes during the simulation.

SM.**step**(...)

Steps a stash of states (by default, the active stash) forward one basic block.

Steps a stash at most *n* steps forward, avoiding addresses listed in *avoid*, until any of the addresses listed in *find* is found (*find* can also be a function which checks the current SimState and returns True or False).

SM.**run**(...)

Similar to explore(), but more rarely used.

To create symbolic inputs we use **claripy**, which is a library used by angr that inherits all basic types from Z3, plus has some more utilities.

Once all is set up, we can start simulating:

```
sim = proj.factory.simulation_manager(initial_state)
   while len(sim.active) > 0:
      print(sim, sim.active)
4
5
6
      # Simulate one block at a time (n=1)
      # Or until we find at least 1 address listed in find=...
8
      sim.explore(find=0x4007B6, n=1, num_find=1)
9
      if len(sim.found) > 0: # Check if we got where we wanted
10
          break
```

angr: state explosion

From malloc.c

```
3742
      bck = victim->bk;
      size = chunksize(victim);
3743
      mchunkptr next = chunk_at_offset(victim, size);
3744
3745
3746
      if ((size <= 2 * SIZE_SZ)</pre>
       (size > av->system_mem))
3747
3748
         malloc_printerr("...");
3749
      if ((chunksize_nomask(next) < 2 * SIZE_SZ)</pre>
          (chunksize_nomask(next) > av->system_mem))
3750
3751
         malloc_printerr("...");
      if ((prev_size(next) & ~(SIZE_BITS)) != size)
3752
3753
         malloc_printerr("...");
      if ((bck->fd != victim)
3754
          (victim->fd != unsorted_chunks(av)))
3755
3756
         malloc_printerr("...");
      if (prev_inuse (next))
3757
3758
         malloc_printerr("...");
3759
```

What happens if we are doing symbolic execution and our program does a call to a very complex library function like for example malloc()?

Many branches grow the stash of active simulation states exponentially! Keeping track of all the active states becomes impossible.

The simulation becomes so slow that it never terminates (or even advances).

angr: state explosion

For common library functions, angr already handles it: it does not analyze their execution, instead it simulates it.

For anything else we need to be careful and control the flow of execution by specifying what to **avoid**.

We can apply symbolic values to a state in many different ways, but the most common are:

Symbolic arguments

Symbolic standard input

Symbolic memory or registers

And for the output, usually we want to see what's on the standard output.

Applying a symbolic value to the **arguments**:

```
argv = ['./prog']
  argv.append(claripy.BVS('arg1', 20*8)) # symbolic first argument
3
  state = proj.factory.entry_state(args=argv)
  simgr = proj.factory.simulation_manager(state)
6
  simgr.explore(find=0xAAAAAA, avoid=0xBBBBBB) # explore...
8
  if simgr.found:
      found = simgr.found[0]
      print(found.solver.eval(argv[1])) # eval
```

Applying a symbolic value to **standard input**:

```
chars = [claripy.BVS('c%d' % i, 8)  for i in range(20)] # 20 bytes
   input_str = claripy.Concat(*chars + [claripy.BVV(b'\n')]) # + \n
   initial_state = proj.factory.entry_state(stdin=input_str) # use as stdin
4
   for c in chars: # make sure all chars are printable
6
       initial_state.solver.add(c >= 0x20, c <= 0x7e)
   simgr = proj.factory.simulation_manager(initial_state)
   simgr.explore(find=0xAAAAAA)
10
   if simgr.found:
       print(simgr.found[0].posix.dumps(0)) # dump content of stdin
```

Applying a symbolic value to **memory**:

```
initial_state = proj.factory.entry_state(addr=0xXXXXXXX)
   var = claripy.BVS('var', 20*8) # 20 symbolic bytes
   initial_state.memory.store(\theta x 4 \theta 1337, var) # store in memory
5
   simgr = proj.factory.simgr(initial_state)
   simgr.explore(find=0xAAAAAA, avoid=0xBBBBBB) # explore...
8
  if simgr.found:
       found = simgr.found[0]
10
       print(found.solver.eval(var).to_bytes(20, 'big')) # eval
```

Angr by default emulates ALL the memory of a process (including memory of libraries). Sometimes this can slow down the simulation, so if we don't need it, we can avoid it by setting *auto_load_libs* to *False*.

```
proj = angr.project.Project('./prog', auto_load_libs=False)
```

Sometimes we want to get some more control on the simulation, or maybe we want to check some register or value in memory at some point of simulation.

To do this, angr makes it possible to **hook certain addresses or symbols** with our own functions (also called SimProcedures).

We can hook a certain **address**, so when it is reached our function is executed:

```
def myfunction(state):
    print('rax:', state.regs.rax) # print contents of some regs
    print('rbx:', state.regs.rbx)
    print('rcx:', state.regs.rcx)
    state.regs.rdx = claripy.BVV(0x1234, 64) # set rdx = 0x1234
    proj = angr.project.Project('./myprog')
    proj.hook(0x401337, myfunction)
```

Or, we can create a SimProcedure and hook a **symbol**:

```
class FakeRand(angr.SimProcedure): # create a custom SimProc
      def run(self):
          # always return 42
          return self.state.solver.BVV(42, 64)
5
  proj = angr.project.Project('./myprog')
  # Hook it to the libc rand() function:
  # NB: we need replace=True because angr already hooks rand
  proj.hook_symbol('rand', FakeRand(), replace=True)
```
